A Dynamic Model of Speech for the Social Sciences∗

Dean Knox† and Christopher Lucas‡

May 10, 2019

Abstract

Auditory cues carry important information—helping politicians convey emotion, signal positions, and mark emphasis—that is lost when analysts transcribe speech recordings, then discard the original sources. We develop the first generative model of the sound and flow of political speech, the model of audio and speech structure (MASS), enabling new empirical tests of long-standing theoretical predictions about communication. Our approach models political speech as a stochastic process shaped by fixed and time-varying covariates, as well as the history of the speech or conversation itself. In an application to Supreme Court oral arguments, we demonstrate how auditory cues convey crucial information—the targeted use of skepticism—that is indecipherable to text models. Results show that justices do not use questioning to strategically signal or manipulate their peers, but rather react genuinely to information discovered in sincere fact-finding efforts. We provide a fast C++ implementation of the model in our easy-to-use R package, speech.

Churchill, The Scaffolding of Rhetoric

1 Introduction

Political science has always been, at least in part, the study of audio. Roosevelt’s fireside chats, Churchill’s World War II addresses to the House of Commons, the Lincoln-Douglas debates, Martin Luther King’s “I Have a Dream” speech: all pivotal moments in modern politics, each occurring in audio. Imagine analyzing these and similarly influential speeches quantitatively; text analysis would represent each no differently than if you, the reader, were the speaker. The delivery would be lost entirely, and questions about the effects of that content would be completely out of reach. In this paper, we propose a new model—the Model of Audio and Speech Structure (MASS)—that opens to statistical inquiry these decades-old questions.

Studies of text in social science often examine corpora that were first spoken, then transcribed. Though methodologically and substantively diverse, text analyses focus exclusively on what people say, while entirely ignoring how those words were spoken. In this article, we develop the first generative model of political speech that explicitly represents how speakers express themselves, the Model of Audio and Speech Structure (MASS). Even without the text of speech, MASS is able to infer new quantities of interest by modeling the sound of speech—the way speakers convey meaning and emotion through their tone of voice—as well as the factors that shape the flow of conversation, or how different tones are deployed. And
because we allow conversation metadata to structure how speakers express themselves, MASS is able to incorporate textual information when it is available, along with any additional fixed or time-varying covariates.

In an application to Supreme Court oral arguments, we demonstrate how our model enables new insights into a particular political context by measuring expressions of skeptical speech on the bench. In contrast to widespread arguments that justices use oral arguments to strategically signal and manipulate their peers, we find that the use of skepticism is more consistent with a model of genuine expression in which justices engage in sincere fact-finding. But beyond this application, MASS can be used to analyze any class of labels that relate to the sound of speech—whether that concerns the speaker’s emotional state, gender, language, or any other imaginable category of interest to the researcher. By modeling the surrounding metadata structure, MASS allows researchers to assess how speech is shaped by characteristics of the speaker, the topic under discussion, or even how one individual responds to the speech of another. In short, MASS allows researchers to study new questions using new quantities of interest conveyed through speech. And while we focus on political science, MASS is broadly useful in any field that studies human speech.

A generative model of audio data is admittedly a departure from more conventional models of political communication. Here, it is useful to note that political science has in fact been concerned with the study of audio data for as long as the discipline has existed, in the sense that the study of speeches, debate, television, radio, and conversation is the study of audio data. And so the question is not “should we study audio data?”—since we already do—but rather, “how should we represent it?” At present, virtually all studies of political speech focus exclusively on a particular representation of audio, the textual content
extracted by transcription. The lost information in the audio channel is substantial. For example, Dietrich, Enos, and Sen (2019) demonstrated that the average pitch of Supreme Court justice questioning is predictive of their subsequent votes, even after controlling for text, important legal covariates, and justice ideology (Martin and Quinn 2002).

While MASS builds on vast literatures in conversation analysis and audio classification, our approach is the first model of its kind in linguistics, signal processing, computer science, and the social sciences. In the study of text, the Structural Topic Model (Roberts, Stewart, and Airoldi 2016; Roberts et al. 2014) demonstrates that incorporating context—that is, explicitly modeling topic choice in terms of covariates—can result not only in improved performance, but also improved inference on the relationships of interest to social scientists. We adopt a similar approach by not only considering the auditory qualities of each utterance in isolation, but also the way in which tone is shaped by potentially time-varying covariates—how leaders project compassion after crises, for example, or whether hostility toward out-group members in a conversation provokes a similarly hostile response. We refer to these temporal effects as changes in the flow of speech, and our model is, as far as we are aware, the first in any field that permits the study of conversation flow. To do so, we model tone as a discrete stochastic process, and then conditional on tone, use a Gaussian hidden Markov model to describe the observed audio for that tone.

1For each justice-case, Dietrich, Enos, and Sen (2019) extract the average pitch of petition- and respondent-directed questions, then analyze the predictive power of “pitch difference” in a random-effects logistic regression on vote. They demonstrate that pitch difference remains a significant predictor even after controlling for the pleasantness of directed words, a battery of legal controls from Black et al. (2011) and Martin-Quinn justice ideal points.
By doing so, MASS enables a range of new empirical analyses. For example, theories of persuasion focus on how logical arguments and cognitive shortcuts shape opinion formation (Festinger 1964, McGuire 1968, Chaiken 1980). However, it is well-established that emotional state can affect cognition (Isen 1984) and political information processing (Redlawsk 2006). Yet to our knowledge, none have considered how passionate argumentation and emotional outbursts can shift the beliefs of other conversation participants, thereby altering the trajectory of political deliberation. Moreover, similar questions abound in other domains. In negotiations, when do threats by hawkish parties lead doves to back down, and when do they escalate tensions? During cable news interviews, do sympathetic or hostile questions shift the information content of an interview? And on the campaign trail, do candidates adapt their tone and self-presentation based on the topic of their speech or their standing in the polls?

MASS is built for precisely this kind of application, facilitating the conception and analysis of new areas of study. Each of these questions fundamentally revolves around conversation or speech flow, the process that MASS is designed to analyze. Our model of speech flow also permits MASS to draw on the sound of surrounding utterances to refine its beliefs about speech tone. Beyond innovation in the model itself, we also provide approaches for MASS model selection and regularization that remove the need for arbitrary researcher choices and allow researchers to exploit a larger range of potentially informative auditory features than past work in signal processing and computer science. Finally, we develop fast estimation procedures that permits bootstrap-based inference on model parameters and quantities of interest.

While we do not discuss our accompanying software package specifically, we implement
our entire workflow in an easy-to-use R package, speech. Our software package contains a fast C++ implementation of the model, as well as flexible functions for audio preprocessing and feature extraction, discussed in Section 3. In general, audio analysis is computationally intensive—our application to Supreme Court oral arguments, for example, analyzed over 44,000,000 rows of data with a multi-step procedure that involved batched processing, parallelization, and stagewise estimation. Our package wraps the entire procedure into a few simple functions to make its implementation broadly accessible.

In what follows, we begin by expanding on the observation that political science already studies audio data, reviewing the many empirical analyses that exclusively analyze the textual dimension of recorded human speech. In Section 3 we then describe how raw audio recordings can be prepared for statistical analysis, much as textual documents are preprocessed. We also review existing approaches for audio classification in signal processing and computer science. Section 4 introduces our model and mathematical notation, then walks through an extended example illustrating how various MASS parameters capture Barack Obama’s rhetorical style in an inspirational campaign speech. We provide a high-level overview of the estimation procedure, reserving technical details for the Appendix. Finally, Section 5 presents a four-part application to expressed skepticism in Supreme Court oral arguments.

2 Political Science Already Studies Audio

Politics occurs in audio. Voters are exposed to political advertisements while watching YouTube (Ridout, Fowler, and Branstetter 2010), coworkers discuss local politics around the
water cooler (Iversen and Soskice 2008), and campaign speeches that go viral alter the courses of elections (Peters and Maheshwari 2018). In each of these examples, political information was first heard. And while the textual component of speech is no doubt important, non-textual communication—the ad’s memorable political jingle, the colleague’s partisan fervor, the candidate’s down-to-earth approachability—is often as important as the text of human speech, if not more.

For example, consider the historic “Daisy” advertisement aired by Lyndon Johnson’s successful campaign in the 1964 presidential election and described as the most effective negative advertisement of all time (Mann 2011). The text of the ad contains a series of numbers and an encouragement to vote for Johnson. Nothing in the transcript suggests a cutthroat, visceral attack ad. But by juxtaposing the voice of a child innocently counting against that of an announcer counting down to a missile launch, followed by a nuclear explosion, the advertisement is threatening to a degree that cannot be appreciated without actually hearing the ad itself. And while the “Daisy” advertisement is a particularly illustrative example, audio is an important component of political communication across a range of contexts.

For example, in Section 5 we apply MASS to speech in Supreme Court oral arguments.

---

2 The full text of the advertisement is “Child: One, two, three, four, five, seven, six, six, eight, nine... Announcer: Ten, nine, eight, seven, six, five, four, three, two, one, zero. Explosion. These are the stakes: to make a world in which all of God’s children can live, or to go into the darkness. We must either love each other or we must die. Vote for President Johnson on November 3rd. The stakes are too high for you to stay home.” (Italicized annotations are included for context and do not appear in transcript.)

3 The advertisement can be viewed at youtube.com/watch?v=2cwqHB6QeUw
to infer a novel measure of the sentiment expressed by justices during the argument stage. Of course, a great deal of existing work analyzes Supreme Court oral arguments. Johnson, Wahlbeck, and Spriggs (2006) demonstrate that justices are more likely to cast “merits” votes supporting lawyers who present higher-quality arguments than the competing party, and Black et al. (2011) demonstrate that a justice’s merits vote reflects the sentiment expressed by that justice during the oral argument, making it less likely that party will prevail in the ultimate outcome. Johnson (2001) further shows that justices use oral arguments to gather information that is used to make substantive policy choices. These analyses all rely on either (1) a manual qualitative assessment of the oral argument or (2) an automated analysis of strictly the text of oral arguments, discarding the tenor of speech. However, tone carries important information about justices’ orientation toward the argument presented before them (Dietrich, Enos, and Sen 2019). And in Section 3, we demonstrate that novel quantities of interest measured with MASS can shed light on these existing questions about judicial behavior.

But beyond the courts, there are countless literatures that study audio data but only analyze the text of speech. To name but a few, research examining candidate debate (Abramowitz 1978; Fridkin et al. 2007), campaign advertisements (Brader 2005; Zhao and Chaffee 1995; Koch 2008; Freedman, Franz, and Goldstein 2004), legislative speech (Proksch and Slapin 2015; Spirling 2016; Lauderdale and Herzog 2016), or television and radio news (Behr and Iyengar 1985; Sobieraj and Berry 2011; Young and Soroka 2012) inherently studies audio data, even if the audio component of speech is discarded after extracting textual transcripts.

Importantly, in addition to improving on existing fields of research, MASS also enables
the study of new questions and quantities of interest. For example, in our application, we study expressions of skepticism, which are virtually impossible to extract from oral argument transcripts alone. And in addition to permitting the analysis of new outcomes, by modeling the dynamics of speech, MASS allows researchers to ask and answer questions about the flow of conversation, such as how a line of argumentation affects downstream discourse. While these sorts of questions are common in theoretical models of sequential games (Dancey and Goren [2010]), they are rarely tested empirically. We suggest that this is due to the absence of a suitable empirical model, and Section 5 demonstrates how MASS can answer questions of this sort.

Like text (Grimmer and Stewart [2013]; Lucas et al. [2015]; Benoit et al. [2018]), audio requires preprocessing before it can be analyzed statistically. In the next section, we provide a straightforward introduction to audio preprocessing.

3 Audio as Data

The number of papers developing and applying methods for text analysis has increased rapidly in recent years (Wilkerson and Casas [2017]). However, little effort has been devoted to the analysis of other components of communication that accompany the textual component of human speech. How can the accompanying audio be similarly treated “as data”? In this section, we now explain how unstructured recordings of human speech can be represented as structured data, then analyzed statistically.

The primary unit of analysis in audio is the utterance: a continuous piece of speech by a single speaker that concludes with a clear pause. These utterances are unequal in length,
but are typically on the order of ten seconds in duration. Within each utterance, we split
the recording into successive moments, which each contain the sound in a narrow window
of time; there are typically 50–100 such moments per second of speech. In our analysis, we
use overlapping windows, each 25 milliseconds in length. Section 4 describes this structure
more formally. In each moment, we then summarize the raw audio with a set of representa-
tive features that are known to convey emotion and tone of voice, drawing on established
literatures in psychology, phonetics, signal processing, and computer science (Verberidis and
Kotropoulos 2006; El Ayadi, Kamel, and Karray 2011). Researchers can easily calculate these
features with a single function in our accompanying R package, which also implements other
useful preprocessing steps. For instance, our package includes functionality for trimming
background noise and interruptions, along with novel approaches for splitting continuous
speech into utterances.

In its most raw form, physical sound is merely a time-varying wave of pressure trans-
mitted through space. These waves are recorded digitally by repeatedly measuring pressure
at frequent intervals—tens of thousands of times per second. Thus, each moment that we
analyze is actually a univariate time series with hundreds of such pressure samples. We
then characterize each moment using a number of auditory features that describe the sound
perceived by a listener. While the features we calculate are more abstract than a textual
representation of the audio, they can still be easily understood. We illustrate selected fea-
tures in Figure 1 by describing an audio source for which that feature is high or low. For
example, some features are simple functions of the raw pressure waveform. Figure 1 illus-
4If we did not use overlapping windows, information that occurs at the window cutoff may
be difficult to observe.
trates one such feature: the “zero crossing rate” (ZCR), which is simply the rate at which the audio wave crosses zero, or neutral pressure. Sibilance (a characteristic of /s/ or /z/) has a particularly high ZCR, whereas vowels have relatively low ZCR. In general, zero crossing rate helps distinguish voiced speech (that employing the vocal cords) from unvoiced speech (that which does not use the vocal track, like /s/). However, some voiced speech nonetheless has a relatively high ZCR. For instance, /z/ is pronounced by vibrating the vocal cords while forming the mouth shape of /s/; both have a relatively high ZCR despite the fact that one is voiced. There is no single feature that distinguishes all sounds, and so we use additional features like “energy” (effectively, loudness), which can be used jointly with ZCR to distinguish the sound of /s/ and /z/.

In addition to features that are simple functions of the raw audio wave, we also calculate features based on its spectrum, which captures (among other things) the contribution of the bass or treble ranges to the overall loudness. To do so, we first decompose the raw audio using a Fourier transform. This maps the audio waveform in each moment from its original representation (pressure varying over time), into a new representation describing the energy in various frequencies. In Figure 1, this is illustrated by the “spectral density” row, which contrasts male and female speech spectra. A number of additional features can be computed from this representation: for example, the Mel-frequency cepstral coefficients (MFCCs) capture its overall shape, and pitch (the dominant frequency) can be extracted from its peaks. These features provide additional emotional information. In English, words may be emphasized with higher sustained pitch or with sharp falling pitch. (Consider “Why are you citing that case?” with “Why are you citing that case?”) Pitch is also higher when speakers are vocally tense, including when speakers are emotionally aroused. Additionally,
we compute various functions of these raw features, including interactions and derivatives that are known to be informative. Appendix Section 2 provides a full list of the features that we construct from the raw vector of audio samples.

In Section 4 we describe how MASS models the way in which auditory features vary with and convey a speaker’s tone of voice. Our approach further accommodates numerous types of contextual factors: from those that are constant over the entire conversation (such as a

Figure 1: **Illustration of selected audio features.** The left column identifies a class of audio summaries that are used to represent the raw audio data. Subsequent columns contain textual descriptions and graphical depictions of audio sources for which the relevant feature has relatively low and high values. For example, ZCR (zero-crossing rate) has a low value for the vowel /a/ and a high value for the consonant /s/. ZCR and energy graphs depict pressure waveforms from machine-synthesized speech recordings; louder sounds are larger in amplitude and hissing sounds are higher in ZCR. Spectral graphs represent the Fourier transform of synthesized recordings; the female voices are concentrated in higher frequency ranges. Pitch is an example of a feature that can be derived from the spectral peaks.
political candidate’s poll numbers on the day of a speech, potentially leading to attacks on an opponent), to time-varying characteristics (the substantive topic under discussion, which necessitates a somber tone), or even variables that depend on conversation history (aggregate anger expressed by previous speakers over the course of an argument, which may make an angry retort more likely).

3.1 Advances Over Existing Approaches

Outside of political science, a large body of research across a range of fields attempts to model the audio of human speech. A common and straightforward approach is to use descriptive statistics (e.g., mean, minimum, maximum, standard deviation) of the audio features described above. This collapses the rich audio data (one feature vector for each moment) into a single flat summary vector per utterance, which can subsequently be input to standard machine-learning models to classify speech mode (Dellaert, Polzin, and Waibel 1996; Mc Gilloway et al. 2000). However, these reduced representations discard enormous amounts of auditory data. To avoid this loss of information, hidden Markov models are commonly used to better model the temporal nature of speech.

MASS builds on these existing approaches in statistics and computer science in two main ways. First, typical HMM-based analyses are only able to use a fraction of the features we incorporate. It is common to arbitrarily select a handful of features and discard the rest. Nogueiras et al. (2001), for example, use just two features\(^5\) and their derivatives within each frame, while Kwon et al. (2003) use 13 total features and Mower et al. (2009) use the

\(^5\)Pitch and energy; see Appendix 2 for a description.
MFCC coefficients and their derivatives. Second, MASS is the first to directly model the flow of speech—that is, the sequence of speech modes—in terms of the meaningful structural features encoded in conversation metadata.

4 A Model of Conversation Dynamics

We now develop a generative statistical model for the audio data that arises from political speech. Section 4.1 formally defines the assumed generative model. The model is then illustrated in Section 4.2 with an extended example drawing on a well-known Obama speech from the 2012 presidential campaign. We first demonstrate how a skilled orator can juxtapose varying rhetorical styles within the same campaign address: a personal and intimate approach to storytelling that contrasts sharply with the fever-pitch, crowd-rousing roar of a turnout appeal. Next, we unpack the way in which these rhetorical styles manifest their distinct auditory signatures. The proposed model is shown to capture the structure of this speech well—not only the macro-level ebb and flow, which is shaped by factors such as the issue under discussion, but also the micro-level changes in enunciation that give the rhetoric its power. After outlining the model, we next turn to estimation and inference in Section 4.3 then discuss practical considerations in the modeling of speech.

4.1 The Model

Suppose we have a conversation with $U$ sequential utterances, each of which arises from one of $M$ modes of speech. (To keep the exposition clear, here we consider the simplified setting in which a single conversation is analyzed. Appendix A presents the general multi-
conversation model, which is essentially identical.) Let $S_u$ denote the speech mode, or tone, of utterance $u$. At a high level, the model contains two levels. The “upper” level, defined in Equations 1–2 characterizes the flow of speech, or the choice of $S_u$. We assume that the conversation unfolds as a time-varying stochastic process in which $S_u$ is chosen based on the conversational context at that moment, encoded in the vector $W_u$. In the “lower” level, we then outline a generative model for utterance $u$’s auditory characteristics, $X_u$. Importantly, this generative model will differ depending on the selected tone of voice selected in the upper model, $S_u$. Equations 3–4 present the lower level more formally. The model is summarized graphically in Figure 2 and we refer readers there for a holistic view of how the various model components fit together.

We begin by modeling speech mode probabilities in each utterance as a multinomial logistic function of conversation context, $W_u$. Note that $W_u$ may include functions of conversation history, such as aggregate anger expressed by previous speakers over the course of an argument—that is, $\sum_{u'<u} 1(S_{u'} = \text{anger})$—which might induce a sharp retort in utterance $u$.

$$
\Delta_{u,m} = \exp (W_u^T \zeta_m) / \sum_{m'=1}^{M} \exp (W_u^T \zeta_{m'})
$$

(1)

$$
S_u \sim \text{Cat}(\Delta_u).
$$

(2)

where $\Delta_u = [\Delta_{u,1}, \ldots, \Delta_{u,M}]$ and $\zeta_m$ is a mode-specific coefficient vector through which $W_u$ affects the relative prevalence of mode $m$. The tone of utterance $u$, $S_u$, is one of the primary quantities of interest, along with the coefficients $\zeta$ that explain why certain tones are used.
more in particular contexts. However, generally speaking, tone is not directly observable to
the analyst; the utterance’s auditory characteristics, $X_u$, is the only available information.
(As we discuss in Section 4.3, the analyst will estimate the model by obtaining a sample of
utterances with human-labeled tone.)

Each $X_u$ is a matrix describing the auditory characteristics of utterance $u$. In this matrix,
the $t$-th row describes the audio at moment $t$ in terms of $D$ auditory features. Thus, the
utterance audio is represented by a $T_u \times D$ feature matrix, where $T_u$ is the length of the
utterance; because utterances may be of differing lengths, $X_u$ and $X_u'$ may have differing
numbers of rows.

To model the audio, we then assume that the $m$ modes of speech are each associated
with their own Gaussian hidden Markov model (HMM) that produces the auditory features
as follows. At moment $t$ in utterance $u$, the speaker enunciates the sound $R_{u,t}$—that is, the
latent state, which may represent phonemes or phoneme groups such as plosives or fricatives.
In successive moments, the speaker alternates through these latent sounds according to

$$ (R_{u,t} \mid S_u = m) \sim \text{Cat}(\Gamma^m_{R_{u,t-1},*}), \quad (3) $$

with $\Gamma^m_{k,*}$ denoting rows of the transition matrix, $[\Pr(R_{u,t} = 1 \mid R_{u,t-1} = k), \ldots, \Pr(R_{u,t} = K \mid R_{u,t-1} = k)]$.

By modeling the usage patterns of different sounds in this way, we approximately capture
the temporal structure that plays an important role in speech. (For example, most latent
sounds are sustained for at least a few moments, and certain phonemes can only occur before
the silence at the end of a word.) In turn, latent sound $k$ is associated with its own auditory
profile, which we operationalize as a multivariate Gaussian distribution with parameters $\mu^{m,k}$
![Diagram of generative model]

Figure 2: Illustration of generative model. The directed acyclic graph represents the relationships encoded in Equations 1–4. In utterance $u$, the speaker selects tone $S_u$ based on “static” (i.e., externally given) time-varying covariates $W_{\text{stat.}}^u$ as well as “dynamic” conversation history covariates $W_{\text{dyn.}}^u$. (In the illustration, $W_{\text{dyn.}}^u$ depends only on the prior mode of speech, but more complex dynamic covariates can be constructed.) Based on the selected tone, the speaker composes an utterance by cycling through a sequence of sounds in successive moments, $R_{u,1}, R_{u,2}, \ldots$, to form the word “mass.” Each sound generates the audio perceived by a listener according to its unique profile; $X_{u,t}$ is extracted from this audio.

and $\Sigma^{m,k}$. Finally, the raw audio heard at moment $t$ of utterance $u$—the signal perceived by a listener—is drawn as

$$X_{u,t} \sim \mathcal{N}(\mu_{S_u,R_{u,t}}, \Sigma_{S_u,R_{u,t}}),$$

which completes the model. Thus, each mode of speech is represented with a rich and flexible HMM that nevertheless reflects much of the known structure of human speech. It is the differences in usage patterns and sound profiles—the Gaussian HMM parameters—that enable human listeners to distinguish one tone or speaker from another.
4.2 Example

Here, we illustrate the model in the context of an excerpt from Barack Obama’s final campaign address in Des Moines, Iowa, on November 5, 2012. While this example represents only a brief scene from an extended campaign, it demonstrates many of the speech dynamics that motivate our model. After showing how MASS parameters map onto the primary theoretical quantities of interest, we outline in detail how an analyst would go about extending the illustration to a full-scale analysis of emotional appeals in campaign rhetoric.

In what follows, we begin with a close examination of two prototypical utterances that represent what we call his “crowd-rousing” roar and his engaging “storytelling” narrative voice. The selected examples are purely demonstrative, and the same approach can be used on any emotion that a candidate might seek to project, such as compassion, humor, or outrage.

We first discuss the sounds of which each utterance is composed, along with their auditory profiles. Consider Obama’s “crowd-rousing” mode of speech—the tone in which he yells to the audience, “I’ve gotta turn out the vote!” He communicates through a sequence of sounds that, simplistically, we might categorize into “vowel,” “consonant,” and “silence.”

---

6The excerpt can be viewed at youtube.com/watch?v=pAV9Tic_bYo&t=1713, along with the full campaign speech.

7We note that sound labels, like topic labels in latent Dirichlet allocation text models, are subjective descriptions of component distributions in unsupervised learning models. However, human speech is highly structured. Across a wide range of applications, we consistently find that HMMs recover states that correspond closely to theoretically motivated phoneme groups.
In Figure 3.C.1, we show that our generative model of crowd-rousing speech mirrors this structure: Vowels (dark red) are sustained for a few moments (horizontally arrayed cells) before Obama transitions to consonants (light red strikethrough) and eventually pauses in silence\(^8\) (white) between words. One such transition is depicted in Figure 3.D.2. Just as a human can recognize phonemes from their auditory characteristics, our model automatically learns to distinguish vowels (based on their higher autocorrelation, as encoded in \(\mu^{rousing,\text{vowel}}\)) from consonants (high zero-crossing rate), as shown in Figure 3.E.

\(^8\)Because each frame describes just milliseconds of audio, the short pauses between words are an observable component of speech.
Figure 3: An illustrative example. Panel A contains an excerpt of Obama’s final campaign speech, utilizing “storytelling” conversation and “crowd-rousing” shouts. Call-outs highlight successive utterance-pairs in which the speaker shifted from one mode to another (B.1), transitioned back (B.2), and continued in the same tone of voice (B.3). Panel C.1 illustrates the use of loudness (text size) and pitch (contours) in a single crowd-rousing utterance: Obama maintains a high and constant volume throughout, with emphatic pitch drops on word endings. In contrast, C.2 shows the far smoother nature of his “storytelling” voice, in which pitch rises and falls gradually and the modulation of volume places emphasis on “voice” and “change.” Call-outs D.1 and D.2 respectively identify sequential moments in which a “storytelling” vowel is sustained (transition from the dark blue sound back to itself, indicating repeat) and the dark red “crowd-rousing” vowel transitions to the light red consonant. Panel E shows the differing auditory characteristics of the “crowd-rousing” vowel and consonant, which are perceived by the listener.
Why does this matter? It is on the basis of these constituent sounds that MASS is able to discern differences between rhetorical styles. As Figure 3.A makes clear, MASS contains a parallel “storytelling” speech model alongside the “crowd-rousing” model. While storytelling also uses vowels and consonants, the auditory profiles of these sounds differ dramatically. Figure 3.C.2 (in which word size reflects decibel-scale energy) demonstrates Obama’s use of modulation when he tells his audience that “one voice can change a room.” Thus, \( \Sigma_{\text{story,vowel}} \) captures higher variance in loudness when compared to crowd-rousing speech (Figure 3.C.1), where every word is shouted at near-constant volume. Differences in average pitch—often a marker of emotional engagement—are represented in the \( \mu \) terms, and shifts in cadence manifest in the \( \Gamma \) matrices.

These models of storytelling and crowd-rousing speech enable analysts to categorize hundreds or even thousands of hours of previously unheard speech. But learning to distinguish “crowd-rousing” speech from “storytelling” speech is only the beginning for MASS. The most important questions in the analysis of political speech relate to its ebb and flow—when and why a speaker chooses to deploy a particular tone. After learning to recognize tone in the lower stage (Equations 3–4), MASS moves on to estimate Obama’s flow of speech by modeling the contextual determinants of speech tone (Equations 1–2). Figure 3.A provides an illustration of how the two examined utterances fit into the broader context of the campaign speech. As Obama approaches the end of his rally, he launches into the story of Edith Childs, the originator of his signature “fired up, ready to go!” campaign chant that animated hundreds of thousands of followers. The story begins with an intimate retelling of their meeting, building momentum before transitioning into a powerful call for turnout volunteers (Figure 3.B.1). Obama then repeats the narrative cycle by quieting down (Figure 3.B.2),
drawing rallygoers in with his soft-spoken speech before ultimately finishing with a dramatic crescendo.

This isolated example, despite comprising only a short excerpt from a yearslong political campaign, nonetheless reveals the cyclical speech patterns—the emotional appeal followed by exhortation to action—that led many observers to describe Obama as one of the most inspirational politicians of the modern era. Figure 4 contrasts his dynamic performance with that of Mitt Romney’s final speech on the same night, the eve of the 2012 election. While Romney clearly seeks to inspire with “the door to a brighter future is open,” the delivery falls flat. On the highest-stakes night of the campaign season, his voice is dully monotone and weakly trails off in volume.

While scholars can easily listen to and compare a few short audio recordings, the amount of time required to digest an entire campaign’s worth of speech—hundreds of addresses, containing tens of thousands of utterances—rapidly grows infeasible. MASS makes it possible to identify broad patterns in the drivers of political speech, analyzing large-scale audio corpora while still incorporating human judgment about tone and expressed emotion. In Section 4.3, we develop a procedure for doing so; Algorithm 1 describes the steps in detail. Broadly speaking, the model learns to identify micro-level patterns, such as those described above, based on a moderately sized training set of human-provided examples. MASS then uses its knowledge (say, of crowd-rousing speech) to crudely categorize every Obama utterance over the multi-year campaign season. Based on their sequence and contextual covariates, MASS identifies patterns in tone usage, then uses these patterns to iteratively refine its utterance

9The excerpt can be viewed at youtube.com/watch?v=CYhS84JbMEU&t=1530, along with the full campaign speech.
Figure 4: **Contrasting candidates.** Utterances from the conclusions of Obama’s and Romney’s election eve speeches on November 5, 2012. Both candidates sought to portray themselves as inspirational leaders. However, their approach to doing so differed tremendously. Obama’s “one voice can change a room” utilized modulation in both his pitch and volume, as the main text discusses in detail. In contrast, Romney’s “the door to a brighter future is open” consists of a monotonic drone—a single, unchanging pitch—that gradually trails off in volume. The sharp distinction illustrates the oratory skill to which Obama’s ultimate success is often attributed.
predictions and the flow-of-speech parameters.

By introducing a conversation-specific covariate for daily polling numbers, an analyst could easily incorporate additional factors into the model: e.g., studying how candidates attempt to come back from a losing position by revamping their public persona. Time-varying covariates representing the current textual topic could be used to assess how candidates modify their speech when talking about wounded veterans, as opposed to climate change or the national debt. And still other covariates might help shed light on how candidates adapt their campaign rhetoric to rural, minority, or hostile audiences. A closer examination of the contexts in which rhetorical tones and projected emotions are deployed—whether they be compassion, indignation, approachability, or fearmongering—may reveal deeper insights about political campaigns, just as the study of text corpora has led to insights about the usage and effectiveness of political attacks.

4.3 Estimation

Here, we describe the procedure by which we estimate the model defined in Section 4.1. At a high level, the estimation incorporates elements of unsupervised and supervised learning as follows. The researcher begins by determining the speech modes of interest, then identifying and labeling example utterances from each class. Within this training set—which might not be a subset of the primary corpus of interest—we consider each mode of speech in turn, using a fully unsupervised approach to learn the auditory profile and cadence of that speech mode. The results are applied to the full corpus to obtain “naïve” estimates of each utterance’s tone, based only on the audio features and ignoring conversational context. We then fit a
model for the flow of conversation, use this to refine the “contextualized” tone estimates, and repeat in an iterative procedure. The specifics of each step are discussed below and in Appendix 1 and the workflow is outlined more formally in Algorithm 1.

Table 1 summarizes the data available for the primary corpus and training set, respectively indicated with $C$ and $T$. The audio characteristics of each utterance, $X$, are observed for both the primary corpus and the training set. However, human-labeled tone of speech, $S$, is only known for the training set. We divide the conversational context into externally given but potentially time-varying “static metadata,” $W^\text{stat.}$, and deterministic functions of conversation history that dynamically capture the prior tones of speech, $W^\text{dyn.}$. The former is known for the primary corpus but may be unavailable for the training set, depending on how it is constructed; the latter is not directly observed for either.

Our ultimate goal is to estimate the conversation flow parameters, $\zeta$, and the auditory parameters of each tone, which we gather in $\Theta^m = (\mu^m, \Sigma^m, \Gamma^m)$ for compactness. In what follows, we also refer to the collection of all tone parameters as $\Theta = (\Theta^m)_{m \in \{1, \ldots, M\}}$. Under
the model described in Equations 1–4, the likelihood can be expressed as

\[ L(\zeta, \Theta | X^T, S^T, X^C, W^{\text{stat}..C}) = f(X^C | \zeta, \Theta, W^{\text{stat}..C}) f(X^T | \Theta, S^T), \]

(5)

with one factor depending only on the primary corpus and another containing only the training set.

As a concession to computational constraints, we estimate the parameters in a stagewise fashion. The auditory parameters, \( \Theta \), are calculated by maximizing the partial likelihood, \( f(X^T | \Theta, S^T) \), corresponding to the training factor, rather than the full likelihood in Equation 5 (Wong 1986). The full likelihood is then maximized with respect to the conversation flow parameters \( \zeta \), conditional on \( \Theta \). The factorization and a detailed discussion of stagewise estimation are presented in Appendix 1.1.

In Appendix 1.2, we detail our procedure for estimating the auditory profile and cadence for each speech mode. First, training utterances are divided according to their tone labels. Because the partial likelihood can be neatly factorized further as \( f(X^T | \Theta, S^T) = \prod_{m=1}^{M} \prod_{u \in T} f(X_u | \Theta^m)^{1(S_u = m)} \), \( \Theta^m \) can be independently estimated for each speech mode with no further loss of information. For all training utterances of speech mode \( m \), a regularized variant of the Baum-Welch algorithm, a standard estimation procedure for hidden Markov models, is used to obtain \( \hat{\Theta}^m \) for the corresponding mode. Each of the resulting \( M \) tone-specific models are then applied to each utterance \( u \) in the primary corpus to obtain the corrected emission probabilities \( f(x_u | \hat{\Theta}^m, S_u = m) \), which represents the probability that the utterance’s audio was generated by speech mode \( m \); this captures the extent to which the audio “sounds like” the relevant training examples. Naïve tone estimates can then be
computed by combining these with the overall prevalence of each tone via Bayes’ rule. The corrective factor, \( \rho \), approximately accounts for unmodeled autocorrelation in the audio features and ensures that the naïve estimates are well-calibrated (for details, see Appendix 1.3). This shared correction, along with the number of latent sounds and strength of regularization, are determined by likelihood-based cross-validation (Laan, Dudoit, Keles, et al. 2004) in the training set.

We now briefly describe an expectation-maximization algorithm for the conversation-flow parameters, \( \zeta \), reserving derivations and other details for Appendix 1.4. An inspection of Equation 5 shows that this procedure will depend only on \( f(\mathbf{X}^c | \zeta, \Theta, W^{\text{stat.}, c}) \), since the remaining term does not involve \( \zeta \). We proceed by augmenting the observed data with the latent tones, \( S^c \), and the conversation-history variables that depend on them, \( W^{\text{dyn.}, c} \). The augmented likelihood, \( f(\mathbf{X}^c, S^c, W^{\text{dyn.}, c} | \zeta, \Theta, W^{\text{stat.}, c}) \), is then iteratively optimized. However, the closed-form expectation of the augmented likelihood is intractable. We therefore replace the full E step with a blockwise procedure that sweeps through the unobserved E-step variables sequentially. Finally, the maximization step for \( \zeta \) reduces to a weighted multinomial logistic regression in which \( \mathbf{1}(S_u = m) \) is fit on \( \mathbb{E}[W_u | S_{u-1} = m'] \) for every possible \( m \) and \( m' \), with weights corresponding to the probability of that transition.

\[ \text{This estimation procedure builds on forward-backward algorithms; interested readers are referred to Appendix 1.2 or standard references such as Zucchini and MacDonald (2009).} \]

\[ \text{The use of this alternative procedure leads to a smaller improvement of the EM objective function than a full E-step. Nevertheless, algorithms using such partial E- or M-steps ultimately converge to a local maximum, just as traditional expectation-maximization procedures do (Neal and Hinton 1998).} \]
Finally, we observe that the unmodeled autocorrelation discussed above renders model-based inference invalid. To address this issue, we estimate the variance of parameter estimates by bootstrapping utterances in the training set, ensuring that dependence between successive moments in an utterance do not undermine our results (Appendix 1.5 discusses potential issues in bootstrapping). The full estimation procedure is outlined in Algorithm 1. Other quantities of interest, such as those discussed in Section 5, follow directly from the conversation-flow parameters, $\zeta$, or the auditory parameters, $\Theta$; inference on these quantities follows a similar bootstrap approach.
Data: Audio features \((X^C, X^T)\), static metadata for primary corpus \((W^{\text{stat.}}, C)\)

Result: Auditory parameters \(\Theta\), conversation flow parameters \(\zeta\)

Procedure:

1. Define problem.
   Analyst determines tones of interest and rubric for human coding.
   Human-coded tone labels are obtained for training set \((S^T)\).

2. Fit auditory parameters \((\Theta)\) by maximizing partial likelihood on training set \((T)\)
   \[
   \text{for speech mode } m \text{ in } 1, \ldots, M \text{ do}
   \]
   \[
   \text{Subset to training utterances labeled as tone } m.
   \]
   \[
   \text{while not converged do}
   \]
   \[
   \text{for utterance } u \text{ in } T \text{ and moment } t \text{ in } \{1, \ldots, T_u\} \text{ do}
   \]
   \[
   \text{for sound } k \text{ in } 1, \ldots, K \text{ do}
   \]
   \[
   \text{Compute emission probability of sound } (m,k) \text{ generating audio } (X_{u,t}).
   \]
   \[
   \text{end}
   \]
   \[
   \text{end}
   \]
   \[
   \text{Predict sound being pronounced at each moment } (R_{u,t}).
   \]
   \[
   \text{Update cadence (usage patterns of constituent sounds, } \Gamma^m).\n   \]
   \[
   \text{for sound } k \text{ in } 1, \ldots, K \text{ do}
   \]
   \[
   \text{Update audio profile of sound } k \ (\mu^{m,k}, \Sigma^{m,k}).
   \]
   \[
   \text{end}
   \]
   \[
   \text{end}
   \]

3. Fit conversation-flow parameters \((\zeta)\) using primary corpus \((C)\), conditional on \(\Theta\)
   \[
   \text{for utterance } u \text{ in } C \text{ do}
   \]
   \[
   \text{for speech mode } m \text{ in } 1, \ldots, M \text{ do}
   \]
   \[
   \text{Compute corrected emission probability of speech mode } m \text{ generating utterance audio data } (X_u), \text{ ignoring context.}
   \]
   \[
   \text{end}
   \]
   \[
   \text{end}
   \]
   \[
   \text{while not converged do}
   \]
   \[
   \text{Predict expected mode of speech for each utterance } (S_u).
   \]
   \[
   \text{Compute expected conversation context for each utterance } (W_u).
   \]
   \[
   \text{Update flow-of-speech parameters } (\zeta).
   \]
   \[
   \text{end}
   \]

Algorithm 1: Stagewise estimation procedure. After defining the tones of interest and obtaining a labeled training set, the analyst conducts cross-validation to set ancillary parameters such as the number of assumed sounds in each mode of speech (not depicted). After fixing the ancillary parameters, the cadence and auditory characteristics of each speech mode are estimated from the training set by an iterative expectation-maximization procedure. These speech parameters are then fixed, and the relationship between conversation context and flow of speech is estimated from the primary corpus. In the multiple-conversation case, the utterance loop in step 3 is nested within an outer loop over conversations. Statistical inference is conducted by resampling \(T\) and repeating steps 2–3 within the bootstrapped training set (not depicted) to obtain bootstrap-aggregated point estimates and bootstrap variance estimates for flow-of-speech parameters and other quantities of interest.
5 An Analysis of Speech in Supreme Court Oral Arguments

In this section, we introduce an original corpus of Supreme Court oral argument audio recordings scraped from the Oyez Project (Cornell 2015). We limit our analysis to the natural court that begins with the appointment of Justice Kagan and concludes with the passing of Justice Scalia, so that the composition of the Court remains constant for the entirety of the period we analyze. The Oyez data contains an accompanying textual transcript, speaker names for each utterance, and timestamps for utterance start and stop times. In addition, we inferred the target side (i.e., petitioner or respondent) of each justice's question based on the side of the most recently speaking lawyer. Additional case data was merged from the Supreme Court Database (Spaeth et al. 2014).

Using Oyez timestamps, we segmented the full-argument audio into a series of single-speaker utterances. As an additional preprocessing step, we drop utterances spoken by lawyers (each of whom usually appears in only a handful of cases) and Clarence Thomas (who spoke only twice in our corpus), focusing on the behavior of the eight recurrent speakers. We also drop the largely formulaic introductory and concluding remarks, along with

\footnote{Dietrich, Enos, and Sen (2019) independently collected the same audio data and conducted an analysis of vocal pitch.}

\footnote{Occasionally, segments are reported to have negative duration, due to errors in the original timestamps. In these cases, we drop the full “turn,” or uninterrupted sequence of consecutive utterances by this speaker.}
utterances shorter than 2.5 seconds. After trimming, the resulting audio corpus contains 407 arguments and 153 hours of audio, comprising over 66,000 justice utterances and 44 million moments.

In the following applications, we consider a tone of substantial importance in the study of courts: the expression of skepticism by a justice, indicating doubt in a lawyer’s arguments. To analyze the use of skepticism, we randomly selected a training set of 200 utterances per justice to hand-classify as “skeptical” or “neutral” speech, allowing our assessments to reflect not only the vocal tone but also the textual content of the utterance. Thus, we define 16 modes of speech—two tones for each of the eight speaking justices. During classification, we dropped the handful of utterances (roughly 5%) in which crosstalk or other audio anomalies occurred, or in rare instances where the speaker’s identity was incorrectly recorded.

Four analyses of skeptical Supreme-Court speech are presented below. First, we demonstrate that MASS recovers a measure of expressed skepticism that has high facial validity, in

14We found that these extremely short utterances contained substantial amounts of crosstalk. However, they also include potentially informative interjections; future work may explore improved preprocessing techniques that do not require discarding this information.

15In the coding process, our guiding classification principle was “If I were a lawyer, would I be happy after hearing this utterance?”

16Because the transcripts attribute each utterance to a speaker, the model’s decision is over whether the current statement by Anthony Kennedy was skeptical or neutral. That is, we do not conduct a joint speaker-recognition and tone-detection task. In the framework outlined in Equations 1–2, this is equivalent to introducing a covariate for the current speaker’s identity, with a corresponding coefficient of $-\infty$ for the 14 speech modes that do not correspond to the current speaker.
the sense that the model’s perception of skepticism (from audio and context) accord closely with human perceptions. Second, we examine the textual content of justice utterances, finding that word frequencies alone are virtually uninformative about expressed skepticism. This reproduces a result that is well-known for other complex emotions, notably sarcasm, and is likely to generalize to other sophisticated tones in political speech such as compassion or authoritativeness. We then demonstrate the workings of the lower-level auditory component of MASS in a third analysis, examining the auditory content of median justice Anthony Kennedy’s skeptical and neutral speech. Here we illustrate how expressed skepticism manifests in terms of loudness, vocal tension, and pitch modulation. Together, these auditory characteristics allow listeners to obtain a clear nontextual signal of Kennedy’s projected emotional state; we then show how speech differs across individuals with a comparison to justice Sotomayor. Finally, we use the full model to analyze the structural determinants of oral-argument skepticism. Using justices’ ideological leanings, their ultimate vote, and a measure of case contentiousness, we test the observable implications of two commonly espoused but conflicting narratives of the Supreme Court decisional process: that justices are highly strategic actors jockeying for influence, on the one hand (Johnson, Wahlbeck, and Spriggs 2006), or alternatively that they are neutral arbiters who respond genuinely to compelling legal arguments (Johnson, Wahlbeck, and Spriggs 2006).

5.1 Facial Validity of Predicted Skepticism

Before proceeding to more substantial results, we first demonstrate the face validity of MASS predictions in a qualitative examination of machine-generated utterance labels. Table 2
presents twenty example utterances that lie in the top decile of predicted skepticism and neutrality. Results suggest high face validity: Utterances characterized by the model as skeptical include gentle mockery and doubtful questions, whereas model-predicted neutral utterances are factual statements and straightforward legal analysis.

<table>
<thead>
<tr>
<th>Skeptical Speech</th>
<th>Neutral Speech</th>
</tr>
</thead>
<tbody>
<tr>
<td>Well, I mean, you don’t know; you’re running away.</td>
<td>You would not be subject to the State suit.</td>
</tr>
<tr>
<td>You’ve – you’ve given us no – no principle the other way.</td>
<td>The one that has the 5-year clearly covers the situation.</td>
</tr>
<tr>
<td>So, I guess they could object on the ground that model is worthless.</td>
<td>But the Authorities Law does authorize the acquisition of other hospitals.</td>
</tr>
<tr>
<td>I mean, of course they would be thinking about that; that was the issue.</td>
<td>And the SEC apparently takes the view that this provision does cover contractors.</td>
</tr>
<tr>
<td>Next step, he goes to the grand jury or someone and says: Jones stole my horse.</td>
<td>But they can’t do that because the statute requires a summary to be understandable and not prolix.</td>
</tr>
<tr>
<td>Counsel, it hasn’t been the focus of the briefing, but you’ve just made it the focus here.</td>
<td>The ball goes back to Congress to do what it will, but it’s just, in the interim, we need a solution.</td>
</tr>
<tr>
<td>Does that make any sense, given the – the class of individuals who are plaintiffs in 16(b) cases?</td>
<td>That sounds much more petition-like than filing a grievance pursuant to a collective bargaining agreement.</td>
</tr>
<tr>
<td>What would happen, under the reasoning of this case, what would happen to the decisions of recess-appointed judges?</td>
<td>Let’s suppose that the district court in Washington moves expeditiously and issues a decision in mid-February.</td>
</tr>
<tr>
<td>Now, that it seems to me could include everything from a spark plug that is deficient in the airplane to a terrorist.</td>
<td>And the other choice is to say that “lawfully made” means it’s made without contravening any provision of the Act, if the Act were applicable.</td>
</tr>
<tr>
<td>Seriously, the unions do not want to have the – they don’t want to be given the status of the exclusive bargaining agent for the employees?</td>
<td>So leaving the language out of it, I would like you to respond to what I would call that purpose-related, fact-related argument by these particular people.</td>
</tr>
</tbody>
</table>

Table 2: **Transcripts of Skeptical and Neutral Utterances.** Left (right) columns contain ten transcripts of utterances in the top 10% of predicted skepticism (neutrality). While MASS is estimated solely on audio data and conversation context, its fitted values accord well with qualitative readings of the utterance text.
5.2 Textual Characteristics of Expressed Skepticism

The fact that humans can validate model-predicted skepticism using utterance text—in extreme cases, at the least—indicates that auditory channel carries emotional information that can be detected by MASS. But it also suggests that skepticism is partially conveyed through textual channels as well. Could tone be extracted directly from the text without the need for complex audio models? To assess whether the auditory channel in fact conveys new information or is merely duplicative, we attempted to predict expressed skepticism using utterance transcripts. For each utterance, word counts were computed after stemming, stopping, and pruning words that appeared in fewer than ten utterances. We first sought to classify skepticism within the human-labeled utterances using a variety of approaches: both pooling justices and considering each justice in turn to allow for speaker-specific word usage, using a wide range of supervised classifiers, and even applying pretrained neural-network models that take sentence structure into account. The results of this exercise were so poor that we do not discuss them further. Next, to rule out the possibility that the roughly 1,600 hand-labeled utterances were too small of a training corpus, we analyze the full corpus. To do so, we treat MASS fitted probabilities of skepticism (based on audio features and conversation context) as the outcome. We then employ a post-LASSO procedure in which a cross-validated LASSO-logistic model is estimated, then an unregularized logistic regression is fit on the selected terms (Belloni, Chernozhukov, and Wei 2016).

The resulting coefficient estimates, plotted in Figure 5, demonstrate that there are extraordinarily few consistent textual indicators of expressed skepticism—the vast majority are statistically indistinguishable from zero at conventional levels. In Figure 6, we arbitrar-
Figure 5: **Textual Signals of Justice Skepticism.** Each panel depicts a regression of MASS-predicted skepticism on word counts. Within each justice’s utterances, candidate terms that may predict skepticism (selected by logistic LASSO) are arrayed on the y-axis. For each term, points and horizontal error bars depict post-LASSO logistic regression estimates and confidence intervals. Thin light blue (thick dark red) error bars reflect 95% confidence intervals that (do not) overlap zero.

illy discard speaker-terms with p-values exceeding 0.05, then investigate the remainder more closely.

For Justice Stephen Breyer, an expressive orator who is by far the most frequently speaking justice, less than 50 such terms exist. For illustrative purposes, we focus on Breyer’s “ah”, “block”, and “lost,” the three terms most heavily associated with his predicted skepticism. While these terms are not obviously associated with negative sentiments, a closer examination sheds light on Breyer’s usage in his freewheeling and at times theatrical questioning:

- A sarcastic retort to an attempt to introduce new arguments, “Ah, now we have ‘sufficiently involved;’”
Figure 6: **Strong Textual Signals of Justice Skepticism.** Each panel depicts a regression of MASS-predicted skepticism on word counts, within a justice’s utterances. Words that predict skepticism are arrayed on the *y*-axis. Reported terms are the subset of post-LASSO terms with post-selection logistic regression confidence intervals (error bars) that do not overlap zero. Highly specific terms (i.e., used in fewer than five cases) are not depicted.

- A direct legal attack, “... this is not adequate State ground that would block Federal habeas;”

- And a question that should strike fear into the heart of any lawyer, “... so I ask you: If it does come about, if it should come about and you lost this case..."

Conversely, Justice Breyer’s neutral-leaning terms include technical terms (“tort,” “brief,” and “procedure”) as well as the fairly innocuous “guess” and “imagine”). While this particular justice’s textual cues are plausible, however, his colleagues are far more difficult to read using word frequencies alone—perhaps because they signal their position in subtle ways, or
perhaps because text is just a poor indicator of expressed emotion. For all other justices, we identify fewer than five informative words through this procedure; moreover, their cumulative predictive power is virtually nonexistent.

5.3 Auditory Characteristics of Expressed Skepticism

The preceding results show that the textual channel is—at best—a noisy, idiosyncratic, or simply weak signal of a justice’s expressed skepticism. What, then, distinguishes skeptical questioning from neutral speech? To demonstrate, we interpret MASS results by investigating the auditory characteristics of median justice Anthony Kennedy’s speech. For Kennedy, we found that a moderately regularized speech model with $K = 3$ latent sounds minimized the total cross-validated likelihood of out-of-sample auditory features. Three well-separated sound classes can be consistently observed across model runs. We subjectively characterize these as “voiced speech” such as vowels, in which the vocal cords vibrate (high autocorrelation); “unvoiced speech,” such as fricatives and sibilants, in which vocal cords are not used (moderate energy and zero-crossing rate); and “silence” (low energy). Using an alignment procedure described in Appendix 3, we identify the three sounds in each bootstrapped model. For illustrative purposes, we compare the auditory characteristics of voiced skeptical speech to voiced neutral speech. The top panel of Figure 7 shows that when speaking skeptically, Kennedy speaks more loudly and with higher average pitch, a consequence of tensed vocal cords. Moreover, his modulation of pitch—which rises during questions and falls sharply during emphatic statements—is markedly larger in skeptical speech, as indicated by its higher pitch variance. We do not, however, observe similar modulation in energy: Kennedy is sim-
ply louder across the board when expressing skepticism. Finally, in the bottom panel, we contrast Justices Kennedy and Sotomayor to demonstrate that these speech dynamics are not entirely unique to individual speakers. While speaker baselines do vary—Sotomayor speaks more softly on average, and her voice is roughly six semitones higher—both communicate their skepticism by elevating pitch and raising their voices, among other auditory cues.
Figure 7: In the top panel, each dark red $\times$ (light blue $\circ$) represents a converged EM run for auditory parameters using a run-specific bootstrap draw of skeptical (neutral) training utterances for Justice Kennedy. Coordinates in a bivariate scatterplot are based on elements of $\mu_{\text{skeptical, voiced}}$ ($\mu_{\text{neutral, voiced}}$) and the diagonal of $\Sigma_{\text{skeptical, voiced}}$ ($\Sigma_{\text{neutral, voiced}}$). For example, the top right panel demonstrates that when speaking skeptically, Justice Kennedy’s voice is markedly louder and exhibits more variation in pitch, relative to his neutral speech. The bottom panel compares the same parameters for Justice Sotomayor’s skeptical (neutral) voiced speech, depicted with dark red $\triangle$ (light blue $\square$). While her voice is generally higher and quieter, on average, Sotomayor also communicates skepticism by elevating her pitch and speaking more loudly.
5.4 Structural Determinants of Expressed Skepticism

We now turn to an open question in judicial politics: what purpose does questioning serve in oral arguments? The answer is subject to considerable debate (Wasby, D’Amato, and Mettrailer 1976; Shapiro 1984; McGuire 1995; Johnson 2001; Shullman 2004; Johnson, Wahlbeck, and Spriggs 2006; Johnson et al. 2009; Epstein, Landes, and Posner 2010; Wedeking 2010; Black et al. 2011; Black, Sorenson, and Johnson 2013); indeed, one Supreme Court justice has even asserted that the act of questioning is neither necessary nor helpful (Thomas 2013). While courts scholars have advanced a number of theoretical accounts of the deliberative process, these explanations can generally be grouped into two broad classes. One narrative holds that justices are shrewd political actors that maneuver to influence the decisions of their peers in pursuit of a desired case outcome (Shullman 2004; Epstein, Landes, and Posner 2010, 2013; Iaryczower and Shum 2012; Iaryczower, Shi, and Shum 2018). However, they are constrained by strong judicial norms against back-room discussions, which foreclose the possibility of private communication. In this account, oral arguments represent an opportunity for justices to strategically signal to their colleagues, with lawyers and their legal arguments serving merely as convenient foils. A second, largely incompatible conception of the decision-making process considers justices as neutral arbiters, each casting a sincere vote according to rules determined by their respective legal philosophies (Johnson 2001; Black et al. 2011; Black, Sorenson, and Johnson 2013). In this latter account, oral arguments provide an opportunity for fact-finding; while justices may reveal their predispositions with a display of doubt, this merely reflects an honest response to compelling or uncompelling legal reasoning.
These competing accounts are challenging to disentangle even under the best of circumstances. This difficulty has been compounded by widespread reliance on a narrowly limited representation of judicial speech: textual transcripts alone. Here, we demonstrate that the discarded audio channel contains information of enormous value to social scientists—and that by modeling the tone it conveys, MASS not only opens the door to new research questions but can also shed new light on existing puzzles.

When and why justices deploy skepticism in oral arguments? Differing theoretical accounts of deliberation suggest very different patterns in the usage of this tone. A model of genuine voting implies when justices communicate their skepticism (to the extent that they make it known at all), it is largely as a natural reaction to poor argumentation. In other words, we should observe generically higher rates of skepticism when justices question lawyers for the side that they find less persuasive. This leads to an observable implication of the genuine-voting theoretical account: when a justice votes against a side, we should observe that this behavior is associated with increased skeptical questioning of the corresponding lawyers (Black et al. 2011; Black, Sorenson, and Johnson 2013).

A strategic-signaling model of deliberation, on the other hand, must account for the fact that many—indeed, nearly half—of all cases are decided unanimously. When all justices agree, no strategy is necessary. There is little to gain from posturing, including acted skepticism. To the extent that experienced justices are able to identify uncontroversial cases from pre-argument legal briefs and lower court decisions, this suggests a key observable implication of the strategic-signaling account: justices should exhibit greater skepticism toward their non-preferred side especially in contentious cases. That is, in cases that are ultimately decided by a 5-4 margin, we should see justices use markedly more skepticism toward the
side they vote against. Forward-looking justices should similarly reduce skepticism toward their own side to avoid damaging its chances in close calls.

A third test concerns the dynamics of oral arguments. In general, justices who are ideologically close will exhibit greater similarity in preferences and judicial perspectives, relative to those who are far apart. When justice $i$ finds a line of legal reasoning to be objectionable (as manifested in an expression of skepticism) it is likely that their ideological neighbor $j$ will find it objectionable as well. The two narratives then diverge in their predictions for $j$’s response. A genuine reaction would be to acknowledge the flaw in reasoning, perhaps following up with further skeptical probing regardless of $j$’s affinity for the lawyer under attack. In contrast, if $i$ is ideologically distant from $j$, then $i$’s skepticism should not provoke much of a response from $j$ due to the relative lack of shared hot-button issues. The strategic account, on the other hand, implies a very different flow of questioning. Suppose that $j$ dislikes the current lawyer. If $j$ were a savvy justice, they should be on the lookout for weaknesses in the opposing side’s arguments, seizing the chance to dogpile when an opportunity presents itself. Ideological distance from $i$—the preceding critic—should not restrain the shrewd operator much, if at all. Indeed, a left-right combination may be a particularly effective blow against the current lawyer.

The strategic narrative suggests a very different sequence of events when $j$’s preferred side comes under attack, however. When ideological neighbor $i$ expresses skepticism, $j$ has an incentive to smooth things over—despite $j$’s ideological inclination to agree with $i$’s points. Thus, the extent to which ideological proximity colors $j$’s response to prior skepticism is a useful point of differentiation. Specifically, we discretize ideology into “left” (Justices Breyer, Ginsburg, Kagan, and Sotomayor) and “right” (Justices Alito, Roberts, and Scalia), setting
Kennedy aside given his unique position at the median. We then test whether a justice agrees with their usual allies—that is, expresses skepticism together—even when that skepticism is directed against their preferred side. If so, this suggests a genuine response; if not, it suggests that justices may be strategically pulling their punches to protect case-specific interests.

The observable implications described above utilize post-argument proxies for justice preferences (vote) and case divisiveness (margin of victory). A natural concern is that a justice’s ultimate vote may be influenced by the course of questioning as well. In this case, persuasion may offer an alternative explanation for patterns in observed skepticism. If strategic justices are always successful in persuading their colleagues, the genuine-voting and strategic-signaling accounts become observationally similar in many cases. While we find this level of persuasiveness to be implausible in light of extensive qualitative work on the courts (Ringsmuth, Bryan, and Johnson [2013], Wolfson [2001]), there is considerable room for future work to improve on our analysis. These improvements may include more rigorous formal modeling of strategic interaction in the deliberative process; collection of better pre-argument proxies for justice predisposition and case controversiality (e.g. circuit court votes); or analysis of natural experiments (e.g. exploiting justice retirements).

Finally, note that in interpreting model parameters and testing theories, we formulate all hypotheses in the following matter: Conditional on justice $i$ speaking, is it more likely that they do so skeptically in one conversation context, as opposed to another?\footnote{This formulation allows us to partial out any shifts in speaker frequencies, which besides being difficult to theorize are also relatively uninteresting.} The competing narratives described above suggest several observable implications for the structural determinants of justice tone—how the side currently being questioned, the tone of the previous

\footnote{\textsuperscript{17}}

\textsuperscript{17}
questioner, et cetera translate into expressed skepticism.

Figure 8 presents results from two MASS specifications. First, we model transition probabilities (i.e., the probability that the next utterance is of justice-tone \( m \)) as

\[
\exp \left( W_u^\top \zeta_m \right) / \sum_{m'=1}^{M} \exp \left( W_u^\top \zeta_{m'} \right),
\]

where the conversation context \( W \) includes the eventual case margin, the ultimate vote of the justice in question, an interaction, and a justice-tone intercept. We then average across justices according to their speech frequency to obtain an average effect. The results show that justices use skepticism against their non-preferred side—either the petitioner or respondent, depending on which one they go on to vote against—at a significantly higher rate, as expected. Contrary to theoretical predictions under strategic signaling, however, we find no indication that the gap between petitioner- and respondent-targeted skepticism depends on the margin of the case decision. That is, the difference in differences is far from significant. We do find that skepticism is generically higher across the board in close cases. These results are consistent with the account that Supreme Court justices are engaged in genuine fact-finding, not a strategic attempt to manipulate their colleagues, and that they particularly seek to get answers right when the stakes are high. (As we note in detail above, we cannot entirely rule out the alternative explanation that some of these results are due to persuasion over the course of oral arguments.)

To probe further, we now turn to the dynamics of argumentation. In an expanded specification, we now incorporate additional binary indicators for whether the preceding speaker belonged to the liberal or conservative wing of the Court, as well as interactions between skepticism in the preceding utterance, ideology of the previous speaker, and vote. As described above, the strategic model of judicial signaling implies that after a peer—any peer—criticizes a justice’s preferred side, the justice should withhold comment or defuse
Figure 8: **Simulated quantities of interest.** Each panel manipulates a single variable from a control value (second element of panel title) to a treatment value (first). Points (error bars) represent estimated changes (95% bootstrap confidence intervals) in skepticism. We average over all other nuisance covariates (e.g., the identity of the next speaker) of the scenario-specific change in outcome, weighting by the empirical frequencies of the nuisance covariates. The top panel shows that justices deploy skepticism more often toward their non-preferred side. The second panel compares close votes to unanimous decisions, demonstrating that justices express more skepticism across the board in the former. However, justices do not attempt to target a particular side in close votes; rather, they simply ask more skeptical questions across the board. Finally, the bottom panel shows that justices mirror the tones of their ideological neighbors, who share similar legal philosophies, even when those neighbors are opposed to the justice’s case-specific voting interests.
tensions with neutral commentary. By the same token, the savvy justice should follow up with a coup de grâce after a colleague finds fault in the disfavored side’s reasoning. We find no evidence that this is true. Rather, our results are highly consistent with a model of genuine expression in which justices concede to the criticisms of ideologically proximate peers, regardless of their case-specific interests. That is, after a liberal (conservative) justice casts doubt on a lawyer’s argument, other liberals (conservatives) on the Court are likely to follow suit even if that criticism undermines their favored side.

6 Concluding Remarks

Political science already studies audio. From campaign addresses to parliamentary debates, many of the field’s recurring questions deal with political speech. And while a great deal of progress has been made in analyzing what was said in these audio recordings, how these words were spoken is often equally or even more important. MASS provides a principled solution for inferring these quantities. And by modeling the flow of speech, MASS directly tests questions about speech dynamics—a phenomenon that is impossible to study with traditional text approaches. Finally, our software makes this computationally complex procedure accessible to everyone.
